# Discrete Fourier analysis for phylogenetic trees 

Martin Ph. Stehno

Department of Physics, University of Illinois at UrbanaChampaign
AbSTRACT Discrete Fourier transformations (DFTs) provide a useful tool to assign a phylogenetic tree (PGT) to an observed frequency of nucleotide patterns in DNA sequences of species. The advantage of this sort of spectral analysis is that it allows global correction for multi-substitution processes [1].

## SPECTRAL ANALYSIS OF PGTS

Two spectras characterize a PGT, the probability spectrum $\mathrm{p}(\mathrm{T})$, and the expected sequence spectrum $\mathrm{s}(\mathrm{T})$. After labelling the edges of the tree in an appropriate way, they are can be related by two steps of transforms using vector functions called Hadamard conjugations. The intermediate vector is called the edge length spectrum. The transformation scheme is given in Fig. 1.

(Hendy \& al., Proc. Natl. Acad. Sci. USA 91 (1994))
Fig.1. Scheme of transformations.

This scheme can be used in two ways. Starting with a probability distribution we can calculate the edge length spectrum and the expected sequence spectrum. On the other hand, given a data set D , we can take the observed sequence spectrum $\mathrm{s}(\mathrm{D})$ (the relative frequencies of character patterns) as an estimate for $\mathrm{s}(\mathrm{T})$. From this we calculate a conjugate spectrum $\gamma(\mathrm{D})$ (the 'corrected partition frequencies') [1, 4]. This will correct for all parallel, multiple, and higher order substitutions. We find the corresponding tree, that is the tree for which $|\gamma(\mathrm{D})-\mathrm{q}(\mathrm{T})|$ is minimal, using a fitting algorithm (e.g. least-squares best fit or 'closest tree algorithm'). Having found the correct tree one is able to reconstruct the probability spectrum and expected sequence spectrum.

## HADAMARD CONJUGATION

A conjugation consists of three transformations that are successively applied. The third transformation is the inverse of the first. The $m \mathrm{~m}$ - Hardamard matrix $\mathrm{H}_{\mathrm{t}}$ is defined as

$$
\begin{aligned}
& \mathrm{H}_{\mathrm{t}}=\mathrm{H}_{1} \otimes \mathrm{H}_{\mathrm{t}-1}, \\
& \mathrm{H}_{1}=\left(\begin{array}{lll}
1 & 1 \\
1 & -1 & ) .
\end{array}\right.
\end{aligned}
$$

The Hadamard transform ${ }^{1}$ is

$$
\mathbf{y}=\mathrm{H}^{-1}(\ln (\mathrm{H} \mathbf{x})),
$$

and its inverse

$$
\mathbf{x}=\mathrm{H}^{-1}(\exp (\mathrm{H} \mathbf{y})), \quad \mathrm{H} \mathbf{x}>0 .
$$

In order to apply the Hadamard transform to our problem, we have to label the tree edges e. We define a binary coding of the four nucleotides by elements of the Klein 4 -group, see Table 1.

| Nucleotide | Code | Substitution |  |
| :---: | :---: | :---: | :---: |
| A | $(0,0)$ | - | - |
| G | $(1,0)$ | A-G | C-T |
| C | $(0,1)$ | A-C | G-T |
| T | $(1,1)$ | A-T | C-G |

Table 1. Binary coding
The substitutions have been chosen to agree with the definition of the Kimura 3ST (or 'three substitution-type') model. This model has 3 parameters: $\mathrm{p}_{1}$ is the rate of transitions of type AG, T/U-C, $\mathrm{p}_{2}$ the rate of transversions of type A-T/U, G-C, and $\mathrm{p}_{3}$ the rate for transversions of type A-C, T/U-G [2].
Now suppose, we have a set N of n taxa (sequence positions, which are compared). A bipartition is a pair of disjoint subsets (A, B) of N. Thus a taxon belongs either to subset A or B. The edges of a simple PGT T for the taxa N with only two characters define a bipartition, the edge bipartition e. Thus each edge is fully described by the labels of the subgroups it belongs to. There are $m=2^{n-1}$ possible bipartitions. Since there are four nucleotides, we have to use quadripartitions rather than bipartitions (four subsets for each site), but employing the scheme of Table 1, we can break the quadripartition $\mathrm{Q}_{\mathrm{i}+\mathrm{mj}}$ down to a first and a second component of the pair $\left(\mathrm{B}_{\mathrm{i}}, \mathrm{B}_{\mathrm{j}}\right)$ of bipartitions. The indices $\mathrm{i}, \mathrm{j}$ for the bipartitions are

$$
\mathrm{i}, \mathrm{j}=2 \mathrm{a}-1+2 \mathrm{~b}-1+2 \mathrm{c}-1+\ldots
$$

where the taxa $\mathrm{a}, \mathrm{b}, \mathrm{c}, \ldots$ have a component, which differs from corresponding taxon on sequence $n$.

## SEQUENCE EVOLUTION MODEL

Three parameters $p_{1}{ }^{i}, p_{2}{ }^{i}$, and $p_{3}{ }^{i}$, the parameters of the Kimura 3ST model, are assigned to each edge $e_{i}$ of the tree T. Together with $p_{0}{ }^{i}=1-p_{1}{ }^{i}-p_{2}{ }^{i}-p_{3}{ }^{i}$ they form the vector $\mathbf{p}$. From $\mathbf{p}$ we can calculate the vector (in i space)

$$
\mathbf{E}=\mathrm{H}_{2}{ }^{-1}\left(\ln \left(\mathrm{H}_{2} \mathbf{p}\right)\right),
$$

with the zerocomponent $\left.\mathrm{E}_{0}=-\left(\mathrm{E}_{1}{ }^{\mathrm{i}}+\mathrm{E}_{2}{ }^{\mathrm{i}}+\mathrm{E}_{3}{ }^{\mathrm{i}}\right)\right)$, which can be thought of as the negative of the expected value of the total number of substitutions along $\mathrm{e}_{\mathrm{i}}$, and the rest of the components correspond to the number of substitutions of type $1,2,3$ respectively.

Analogously the transform

$$
\mathbf{p}=\mathrm{H}_{2}^{-1}\left(\exp \left(\mathrm{H}_{2} \mathbf{E}\right)\right),
$$

[^0]will give us back the probability spectrum $\mathbf{p}$.
We obtain the edge length spectrum $\mathbf{q}(\mathrm{T})$ from the $\mathrm{E}_{\mathrm{j}}$ 's using
\[

$$
\begin{gathered}
\mathrm{q} 0=-\Sigma_{\mathrm{i}, \mathrm{j}} \mathrm{E}_{\mathrm{j}}^{\mathrm{i}} \\
\mathrm{q}_{\mathrm{i}}=\mathrm{E}_{1}^{\mathrm{i}}, \\
\mathrm{q}_{\mathrm{mi}}=\mathrm{E}_{2}{ }^{\mathrm{i}}, \\
\mathrm{q}_{\mathrm{i}+\mathrm{mi}}=\mathrm{E}_{3}{ }^{\mathrm{i}}, \\
\text { and } \mathrm{q}_{\mathrm{j}}=0 \text { otherwise. }
\end{gathered}
$$
\]

This spectrum contains all the information about the edge lengths and therefore the substitution probabilities of each type. Finally, we calculate the expected sequence spectrum

$$
\mathbf{s}(\mathrm{T})=\mathrm{H}_{2(\mathrm{n}-1)^{-1}}\left(\exp \left(\mathrm{H}_{2(\mathrm{n}-1)} \mathbf{q}(\mathrm{T})\right)\right) .
$$

The inverse of this equation is needed to obtain the conjugate spectrum $\gamma(\mathrm{D})$ from the data setD,

$$
\gamma(\mathrm{D})=\mathrm{H}_{2(\mathrm{n}-1)}{ }^{-1}\left(\ln \left(\mathrm{H}_{2(\mathrm{n}-1)} \mathrm{s}(\mathrm{D})\right)\right) .
$$

If the sites evolve at different rates, we must replace the logarithm by the functional inverse $\varphi$ of the momentum-generating function for the distribution, thus

$$
\gamma(\mathrm{D})=\mathrm{H}_{2(\mathrm{n}-1)}{ }^{-1} \varphi\left(\left(\mathrm{H}_{2(\mathrm{n}-1)} \mathrm{s}(\mathrm{D})\right)\right) .
$$

## DISCUSSION

The Hadamard conjecture is an alternative to more conventional methods of PGT construction. It has been found particularly useful for analysing the performance of different phylogenetic methods under suitable conditions. [2]
Recently a new idea for a dynamical picture of phylogenetics has been proposed [5]. It is based on an analogy between quadripartition and a momentum space representation of perturbation theory for a many-body quantum field theory on a hypercubic lattice. The quantum field theory formalism was introduced to solve the statistical masterequations for the time-evolution of the probability functions [6]. In this context the Hadamard inversion techniques could provide a position space formulation of the theory.
